

Demand Propagation Through Traded Risk Factors^{*}

This version: June 2025. Most recent version [here](#).

Abstract

We develop an arbitrage-free framework to characterize how shocks to one financial asset reprice others through shared exposure to traded, non-diversifiable risk factors. We apply it to study demand shock propagation in foreign exchange (FX). Using a novel technique that jointly analyzes trading flows and returns, we first identify three traded risk factors—Dollar, Carry, and a new factor linked to active euro–yen trading—that together explain 90% of the non-diversifiable risk borne by FX intermediaries. These risk factors transmit shocks across currencies through shared exposures, as factor prices respond to demand shocks. We then estimate their price sensitivity to demand using an instrumental-variable strategy enabled by our factor construction, which isolates factor-specific variation from correlated cross-section. We find that factor prices rise by 5–30 basis points per \$1 billion of net demand, underscoring intermediaries’ limited risk-bearing capacity. Finally, we quantify demand propagation across 17 currencies and 6 asset classes, showing that interventions targeting a single currency can propagate globally, moving both other exchange rates and non-currency assets with currency risk exposure.

1 Introduction

A defining feature of modern financial markets is their tight interlinkages. Episodes such as the Global Financial Crisis of 2007–2009 serve as stark reminders that shocks originating in one corner of the market can rapidly propagate across the globe (e.g., [Allen and Gale, 2000](#); [Pavlova and Rigobon, 2008](#)). One class of shocks that arises frequently in asset markets are demand shocks. Although they do not reflect new fundamental information, demand shocks nonetheless move prices powerfully (e.g., [Lee, Shleifer, and Thaler, 1991](#); [Froot and Ramadorai, 2008](#); [Koijen and Yogo, 2019](#)). In an interconnected system, these shocks rarely affect only a single asset. For example, when a central bank intervenes in the foreign exchange market, the target currency moves—but so do many others. Which currencies react, and by how much? Answering these questions is essential for understanding how shocks propagate and for designing effective policy interventions and responses.

Yet the very linkages that enable such propagation also make it difficult to measure. In principle, every asset could be affected by shocks to every other, thus flexibly capturing propagation across a market with N assets would require estimating N^2 cross-impact coefficients. However, genuine asset-specific demand variation is scarce: investor flows often arrive in correlated baskets, rebalancing typically affects multiple assets at once, and index-linked trades tend to move many markets together. Progress therefore hinges on imposing structure, a task complicated by the high degree of interconnectedness and substitutability among financial assets ([Fuchs, Fukuda, and Neuhaus, 2025](#); [Haddad, He, Huebner, Kondor, and Loualiche, 2025](#); [Koijen and Yogo, 2025](#)).

In this paper, we propose an arbitrage-free framework for quantifying demand propagation. We argue that when a single asset is hit by a demand shock, marginal investors end up carrying additional exposure in a small set of traded, non-diversifiable risk factors; the resulting shift in factor demand moves factor prices, which in turn reprices all assets that load on those factors. Two well-established insights underpin the framework. First, asset prices co-move because investors care about non-diversifiable risks, which can be represented as factor portfolios or “factors” ([Markowitz, 1952](#); [Ross, 1976](#); [Kozak, Nagel, and Santosh, 2018](#)). Second, these factors are inelastic: small quantity changes generate large price movements ([Gabaix and Koijen, 2021](#); [Li and Lin, 2022](#)). Our contribution is to link factor inelasticities with each asset’s exposure to those factors, thereby imposing an arbitrage-free structure on the N^2 asset-level demand propagation problem.

While the underlying intuition is clear, operationalizing the framework raises two key challenges. First, which factors actually transmit demand shocks? Risk factors are typically proposed to explain common variation in returns ([Ross, 1976](#)). But a singular focus on

returns ignores quantities, and the resulting risk factors need not correspond to those that investors actually trade—and that are therefore exposed to demand shocks. We bridge this gap with a new method that jointly analyze price and quantity data. This method uncovers what we call “*traded risk factors*”: portfolios that explain the majority of non-diversifiable risk borne by marginal investors when absorbing trading flows, and that therefore serve as the principal conduits for demand-shock propagation.

Second, how does propagation work when multiple risk factors are at play? Even with $K \ll N$ factors, if a shock to one factor could reprice others, a fully flexible model still requires K^2 parameters. Moreover, it is challenging to map all K^2 parameters to economic primitives. In response, we construct the traded risk factors to be orthogonal. By design, each factor behaves like a standalone asset, such that demand shocks to one factor do not affect the price of another. Hence, propagation at the factor level is governed by just K parameters, with each parameter directly capturing the marginal investors’ aversion to absorbing additional risk in that factor. Under no-arbitrage, the cross-impact between any two assets depends on: (i) *Risk reallocation*: how a demand shock to the first asset alters net demand for each factor, (ii) *Factor repricing*: how each factor’s price responds to risks induced by its own demand, and (iii) *Pass-through*: how the altered factor prices change second asset’s price.

We apply our framework to study demand propagation in foreign exchange (FX). Demand shocks, such as those caused by central-bank interventions, corporate hedging, and index rebalancing, hit currencies almost daily. At the same time, no currency market operates in isolation. Sophisticated intermediaries absorb customer trades and pass any resulting inventory risk among themselves through a dense inter-dealer network. This constant reshuffling leaves returns to align with a handful of common factors (Lustig, Roussanov, and Verdelhan, 2011), underscoring the role of non-diversifiable risks in driving currency co-movement. What has been missing is data on the underlying trading flows. A novel dataset that records the net positions handled by more than 70 major intermediaries across 40 currency pairs fills this gap, which we harness to reveal the risks FX intermediaries truly bear.

Our inquiry starts with identifying the most important non-diversifiable risks in FX trading: the traded risk factors. To do so, we jointly analyze the daily trading flows between customers and intermediaries across 17 major currencies and the corresponding panel of currency returns. Unlike merely *tradable* factors, these *traded* factors capture the non-diversifiable risks that investors actually trade.¹ The two most prominent traded FX factors

¹“Tradable factors” are risks that can be traded because they track portfolios that can be bought or sold. “Non-tradable factors” describe risks that can be measured but not directly traded, such as the global economy. The “tradable” label does not require that the corresponding portfolios to be actually traded.

resemble the well-known Dollar and Carry factors. Additionally, we uncover a Euro-Yen Residual factor that captures the residual risks borne by intermediaries when accommodating active customer trading between the euro area and Japan, even after hedging the Dollar and Carry factors. This new factor delivers a Sharpe ratio comparable to that of the Carry factor. Analyzing trading data jointly with return adds valuable insight: for one, it recovers the Carry factor without first sorting currencies by interest rates, as in [Lustig, Roussanov, and Verdelhan \(2011\)](#); for another, it uncovers risk dimensions that matter for trading—and thus for demand propagation—beyond the unconditional risks identified by analyzing returns alone. Our approach also contrasts with analyses based solely on flows, which uncovers the most heavily traded currency pairs but do not reveal the underlying risk factors. Together, the top three traded FX factors account for 90% of the trading-induced non-diversifiable risks in our sample, are economically interpretable, and remain stable over time. Beyond explaining trading-induced risks, these factors reveal intermediaries’ otherwise unobserved risk exposures. For instance, using net trading flows into the Carry factor, we estimate that intermediaries accumulated \$0.8 trillion in Carry trade exposure from 2012 to 2023.

Next, we investigate how the price of each traded FX factor responds to its own trading-induced risks. To estimate this price sensitivity from observed trading flows and returns, we use instrumental variables (IVs). A valid instrument must satisfy three conditions: relevance, exogeneity, and exclusion restriction. In our context, the ideal instrument should affect trading demand without carrying information about fundamentals, and crucially, the instrument should affect a factor’s price only through demand for that factor. This last requirement is difficult to satisfy in general, as financial assets are tightly linked: any instrument that shifts demand for one asset is likely to shift demand for others that are not included in the regression. Such spill-overs of demands feed back into the original asset’s price via cross-impacts, contaminating the estimate of own price elasticity. However, because our traded FX factors are constructed to be mutually orthogonal, each factor’s return is, by design, affected only by its own trading demand. As a result, even if an instrument induces trading across multiple factors, we can consistently estimate a factor’s price sensitivity by simply regressing its return on its own instrumented demand. [Haddad, He, Huebner, Kondor, and Loualiche \(2025\)](#) also highlight that asset interlinkages can complicate IV estimation, and address the issue by regressing each factor’s return on the instrumented demand of all factors. We achieve the same goal through orthogonality, which allows us to isolate price sensitivity without taking a stance on the complete set of risk factors.

We use as instrumental variables the *week-ahead announcements* of the offering amount at upcoming sovereign bond auctions in the U.S., Australia, Canada, France, Germany, Italy, Japan, and the U.K. These sovereign auctions often attract foreign investors who

need to convert currencies to participate, making the instruments relevant. Importantly, because these auctions are typically forward-guided, the week-ahead announcements contain limited new information, making the instruments plausibly exogenous and satisfying the exclusion restriction. For instance, in the U.S., the Treasury Borrowing Advisory Committee (TBAC) releases two-quarter-ahead recommendation on auction amounts; the subsequent week-ahead announcements and the eventual auctions exhibit little deviation from these recommendations (Rigon, 2024). Although the timing and the amount of bonds auctioned are well anticipated, such predictable demand shocks could still affect prices when realized (Vayanos, 2021; Hartzmark and Solomon, 2024). We find that compensating intermediaries for absorbing a \$1 billion non-diversifiable demand shock requires price increases of 5 basis points (bps) for the Dollar, 9 bps for the Carry, and 29 bps for the Euro-Yen Residual. These contemporaneous price responses fully revert within a month, supporting the interpretation that our instruments capture uninformed shocks. As the price impact from trading is mean-reverting, trading volatility explains a sizable share of short-term return variance—about 10–35% of the 1-week return, but considerably less at longer horizons—5–15% of the 1-month return.

Our results imply that FX intermediaries have relatively limited risk-bearing capacity. The traded FX factors exhibit higher price sensitivity to demand shocks than the U.S. equities market factor.² Supporting the interpretation that higher price sensitivity reflects intermediaries’ more limited risk-bearing capacity, we also find evidence of state-dependence. Specifically, when intermediaries’ public equity returns are high, the Dollar factor’s price sensitivity is low. As equity returns likely capture variations in intermediaries’ wealth, our findings are consistent with greater wealth leading to greater willingness to bear risk (He and Krishnamurthy, 2013; Brunnermeier and Sannikov, 2014). One potential reason for FX intermediaries’ limited risk-bearing capacity is the relatively limited arbitrage capital in this highly specialized market. Although there is large daily trading volume in FX, up to 75% of trades are between intermediaries (BIS, 2022), leaving a more modest pool of capital to absorb demand shocks. Differences in arbitrage capital may also explain the cross-factor variation in price sensitivity, with lesser-known factors such as the Euro-Yen Residual attracting less arbitrage capital and exhibiting greater price sensitivity.

Having identified the most important traded FX factors and each factor’s price sensitivity to risk, we use these findings to trace out demand propagation across currencies. When intermediaries accommodate a demand shock to one currency, they bear additional non-

²Gabaix and Koijen (2021) find that a 1% larger trading demand shock to the entire U.S. stock market increases price by 5%. Such a shock can be interpreted as a shock to the market factor. The average market capitalization between 2012 and 2022 is about \$31.7 trillion. A \$1 billion demand shock in our sample period therefore raises the price of the market factor by about 2 bps.

diversifiable risks captured by the traded FX factors. These risks then affect the prices of the traded FX factors in proportion to these factors’ price sensitivities. Finally, the law of one price ensures that prices of other currencies that share those exposures also adjust and such exposures can be measured as betas or factor loadings. We quantify this demand propagation through cross-multipliers, which measure how a demand shock to one currency affects the price of another, holding the demand shocks to all other currencies constant.³

We uncover rich patterns of cross-currency substitution arising from exposures to the three traded risk factors. Currencies exhibit strong demand propagation when they share the same sign of loading to a factor and modest propagation when they have opposite signs. For instance, we find a large cross-multiplier between the Australian dollar (AUD) and the Canadian dollar (CAD) because both currencies have the same sign of loadings on all three traded FX factors, making them close “substitutes” whose prices co-move strongly. In contrast, the cross-multiplier between the Japanese yen (JPY) and either AUD or CAD is small because JPY has the opposite loading on the Carry factor, allowing these currencies to hedge each other by reducing intermediaries’ exposure to the Carry factor. Similarly, while the euro (EUR) and JPY are both low-interest-rate currencies and act as “substitutes” with respect to the Carry factor, they are on opposite sides of the Euro-Yen Residual factor, making them “complements” for that factor. As a result, we estimate only a modest cross-multiplier, implying muted demand propagation between EUR and JPY.

Additionally, we find that five major non-currency assets also load on the traded FX factors, allowing demand shocks to propagate across markets through shared currency risk. We study U.S. Treasury bonds (Treasurys), corporate bonds, options, CDS, and commodities. The traded FX factors explain approximately 30% of each asset class’ return variance. Consequently, a demand shock to, say, corporate bonds generates non-diversifiable risks as captured by the traded FX factors. These risks affect the prices of traded FX factors and, in turn, the prices of options and other assets that load on the affected factors. Demand shocks transmitted through the traded FX factors have the smallest price effect on U.S. Treasuries, consistent with the depth and liquidity of the Treasuries market. Notably, only Treasuries exhibit negative cross-multipliers with other assets, reflecting Treasuries’ “safe haven” status. In our framework, this safe-haven property arises because Treasuries load on the Carry factor with a uniquely negative sign, making them an effective hedge against other asset classes during shifts between “risk-on” and “risk-off” regimes.

Our paper contributes to the understanding of demand propagation across assets marked

³Because *idiosyncratic* risk does not transmit demand shock across different currencies, our three factors home in on the part that does: *systematic* risk. That said, our results should not be interpreted as capturing the total multipliers across all currencies. Doing so would require measuring both price responses to systematic risk *and* price responses to idiosyncratic risk while holding systematic risk constant.

by high degree of interconnection, substitutability, and complementarity (Fuchs, Fukuda, and Neuhaus, 2025; Haddad, He, Huebner, Kondor, and Loualiche, 2025; Koijen and Yogo, 2025). In essence, we introduce a new structure to the daunting $N \times N$ cross-impact coefficients by appealing to a handful of orthogonal risk factors that are known to drive price co-movements. Our approach complements and contrasts with other structural approaches undertaken to study demand shocks. One existing approach maps the effect of demand to asset characteristics via micro-founded demand systems (e.g., Koijen and Yogo, 2019, 2020; Bretscher, Schmid, Sen, and Sharma, 2022; Chaudhary, Fu, and Li, 2023; Jiang, Richmond, and Zhang, 2024). Another approach links the price effect of demand shocks to pairwise return covariances (e.g., Vayanos and Vila, 2021; Kodres and Pritsker, 2002; Pasquariello and Vega, 2015; Davis, Kargar, and Li, 2023; Greenwood, Hanson, and Vayanos, 2023; Jansen, Li, and Schmid, 2024). Similar to these approaches, we take seriously the factor structure in asset returns, which is shown to be empirically important even in the presence of noise trading (Kozak, Nagel, and Santosh, 2018). At the same time, we innovate on two key dimensions. First, because we are interested in propagation across assets, we directly study the effect of demand shocks to traded, non-diversifiable risks. Second, we allow possibly different risk-bearing capacity, and thereby price sensitivity, toward different risks. Consequently, we are able to generate flexible cross-asset dynamics that allow assets to be substitutes with respect to one risk but complements with respect to another.

Our paper also extends the literature on exchange rates by developing a novel approach to quantifying the price response of trading flows through risks. Beyond conveying information (e.g., Evans and Lyons, 2002; Pasquariello, 2007; Froot and Ramadorai, 2008), trading influences prices by increasing the non-diversifiable risks that marginal investors must bear. Our contribution is to recover risk factors that investors empirically deem important by analyzing their trading behavior together with return data. This revealed-preference approach differs from, and complements, the literature’s typical method of conjecturing relevant state variables based on economic intuition, constructing factors from those variables, and then testing these factors’ cross-sectional pricing power.⁴ We find that the two most traded FX factors, the Dollar and the Carry, are the same factors that price unconditional FX returns (Lustig, Roussanov, and Verdelhan, 2011). We moreover introduce a new Euro-Yen Residual factor, which delivers a Sharpe ratio comparable to that of the Carry factor and is priced conditionally on demand shocks. Beyond identifying traded risks in FX, we uncover new evidence demonstrating the pivotal role of FX intermediaries’ risk-bearing capacity in how

⁴For example, Fama and French (1993) identify size and value as key state variables for determining expected returns, sort stocks by these variables to build the size and value factors, and then show that these factors price the cross-section of expected returns.

risks are priced in trading. Our findings complement existing research on priced risk factors in FX markets (e.g., [Bansal and Dahlquist, 2000](#); [Lustig and Verdelhan, 2007](#); [Hassan and Mano, 2018](#); [Korsaye, Trojani, and Vedolin, 2023](#)) and offer fresh insights into the role of trading-induced risks in driving price co-movements across currencies, between FX and other asset markets, as well as in transmitting monetary policy shocks (e.g., [Jiang, Krishnamurthy, and Lustig, 2021](#); [Camanho, Hau, and Rey, 2022](#); [Chernov and Creal, 2023](#); [Gourinchas, Ray, and Vayanos, 2024](#); [Loualiche, Pecora, Somogyi, and Ward, 2024](#); [Liao and Zhang, 2025](#)).

More generally, our paper augments the intermediary asset pricing and the microstructure literature, both of which emphasize intermediaries’ limited risk-bearing or balance-sheet capacity as a driver of asset price responses to customers’ demand shocks (e.g., [Ho and Stoll, 1981](#); [Grossman and Miller, 1988](#); [Gabaix and Maggiori, 2015](#); [He and Krishnamurthy, 2017](#); [Kondor and Vayanos, 2019](#); [Haddad and Muir, 2021](#); [Du, Hébert, and Huber, 2023](#); [Du, Hébert, and Li, 2023](#)). While we share this focus on intermediaries and the frictions they face, our approach differs in emphasizing that intermediaries’ pricing decisions are shaped by non-diversifiable risks aggregated across all assets, rather than analyzing the risks of individual assets in isolation. In this sense, our perspective aligns with the foundational insights of [Markowitz \(1952\)](#), [Sharpe \(1964\)](#), and [Lintner \(1965\)](#), where non-diversifiable risks are the primary concern in asset price determination.

The next section presents our theoretical framework. Section 3 introduces the data sources and Section 4 identifies the traded FX factors. Section 5 examines the unconditional and conditional pricing properties of the traded FX factors. Section 6 explores how these factors propagate demand shocks across currencies and other asset classes. Section 7 concludes.

2 Theoretical Framework

This section begins by introducing the model setup. It then describes the construction of the traded risk factors, the solution for these factors’ price sensitivity to trading-induced risks, and the mapping from factor-level price sensitivity to demand propagation across individual currencies.

2.1 Model Setup

There are three periods: $t = 0$, $t = 1$, and $t = 2$; and there are $N + 1$ currencies, where the last currency serves as the numeraire. Customers buy or sell any pair of the $N + 1$ currencies. These trades could be motivated by demand shocks (e.g., preference shocks) or private information. All customer trades are accommodated by a mass μ of competitive

intermediaries. For $n = 1, \dots, N$, the return of currency n from time 0 to time 1 is r_n , which is defined as the return from borrowing one unit of the numeraire at its risk-free rate, converting it to currency n at time 0, investing at currency n 's risk-free rate from time 0 to 1, and then converting it back to the numeraire at time 1. We stack r_n into an $N \times 1$ vector as $\mathbf{r} = (r_1, r_2, \dots, r_N)^\top$.⁵ Similarly, R_n denotes the return of currency n between time 1 and time 2, which we stack into an $N \times 1$ vector $\mathbf{R} = (R_1, R_2, \dots, R_N)^\top$. We assume there are no redundant currencies, so the matrix $\text{var}(\mathbf{r})$ has full rank, and we assume that the return covariance structure remains stable over time, such that $\text{var}(\mathbf{r}) = \text{var}(\mathbf{R})$.⁶ Our goal is to study the price response of customer demand shocks between time 0 to time 1, holding constant the trading between time 1 and time 2. We empirically map the interval between time 0 to time 1 to a week. Time $t = 2$ represents the long term, where currency prices are no longer affected by demand shocks between time 0 and time 1; reaching this stage may take months in reality.

2.2 Factor Construction

We want to study trading-induced risks that intermediaries bear at the margin. We thus aim to identify a few factors that maximally explain the non-diversifiable risks induced by the aggregate trading flow. Using the U.S. dollar (USD) as the numeraire currency, we first decompose all trades between time 0 and 1 into trades against USD, and express the aggregate trading flow as $\mathbf{f} = (f_1, f_2, \dots, f_N)^\top$, where f_n is the net customer buying flow for currency n against USD.⁷ For any given factor $\mathbf{b}_1 = (b_{1,1}, \dots, b_{N,1})^\top$, where $b_{n,1}$ represents the weight of currency n in this factor,⁸ currency n loads on the factor with $\beta_{n,1} = \text{cov}(r_n, \mathbf{b}_1^\top \mathbf{r}) / \text{var}(\mathbf{b}_1^\top \mathbf{r})$. When intermediaries accommodate a currency-level trading flow, f_n , they effectively bear a factor-level trading flow of size $f_n \beta_{n,1}$, along with other risks uncorrelated with the factor. Given that there are N currencies, intermediaries can offset the factor-level trading flow across different currencies, leaving a non-diversifiable factor-level

⁵Throughout this paper, bold font is used to denote matrices and vectors, and $\mathbf{A}^\top$ represents the transpose of $\mathbf{A}$.

⁶All our theory holds if we instead assume the more general form $\text{var}(\mathbf{r}) = L \text{var}(\mathbf{R})$, for some positive constant L .

⁷Specifically, if a customer buys currency n by selling currency m , we record it as a positive trading flow for currency n from USD and a negative trading flow for currency m from USD. In Supplemental Appendix A, we prove that the construction of traded risk factors remains invariant to the choice of the numeraire currency.

⁸By definition, the weight of USD in this factor is $-\sum_{n=1}^N b_{n,1}$.

flow of amount⁹

$$q_1 = \sum_{n=1}^N f_n \beta_{n,1} = \text{cov}(\mathbf{f}^\top \mathbf{r}, \mathbf{b}_1^\top \mathbf{r}) / \text{var}(\mathbf{b}_1^\top \mathbf{r}). \quad (1)$$

Note that for any given factor (as defined by the portfolio weights $\mathbf{b}_1$), the factor-level trading flow q_1 varies in proportion to the currency-level trading flow f_n , and this relationship depends on the factor being considered, as varying $\mathbf{b}_1$ changes the beta ($\beta_{n,1}$) of a currency to a factor.

The last equality in (1) admits a “portfolio beta” interpretation. Here, $\mathbf{f} = (f_1, f_2, \dots, f_N)^\top$ represents the marginal portfolio position intermediaries take when accommodating the trading flow, and $\mathbf{b}_1$ is the factor portfolio under consideration. Equation (1) shows that q_1 is simply the beta of the marginal portfolio $\mathbf{f}$ with respect to the factor portfolio $\mathbf{b}_1$. The factor flow q_1 quantifies how much intermediaries adjust their exposure to factor $\mathbf{b}_1$ as a result of accommodating customer flow.

We next specify the problem that pins down the most traded risk factors. Because returns are defined per dollar, $\beta_{n,1}$ measures the additional factor exposure in *dollars* from one *dollar* invested in currency n . Thus, when summing the currency-level flows f_n using the beta weights in (1), these flows must be measured in dollars,¹⁰ and the resulting factor flow q_1 is likewise expressed in dollars. A one-dollar flow into factor $\mathbf{b}_1$ adds extra risk of $\text{var}(\mathbf{b}_1^\top \mathbf{r})$. As q_1 varies, the amount of extra risk varies accordingly. Hence, the most traded risk factor is determined by finding the portfolio weights $\mathbf{b}_1$ that produce the largest trading-induced risk:

$$\max_{\mathbf{b}_1} \text{var}(q_1) \text{var}(\mathbf{b}_1^\top \mathbf{r}). \quad (2)$$

Even though a portfolio can be freely levered, this objective function is scale invariant.¹¹

We construct the second factor $\mathbf{b}_2$ by requiring that the second factor has an uncorrelated return with the first and maximizes the same objective,

$$\begin{aligned} \max_{\mathbf{b}_2} \text{var}(q_2) \text{var}(\mathbf{b}_2^\top \mathbf{r}) \\ \text{s.t. cov}(\mathbf{b}_1^\top \mathbf{r}, \mathbf{b}_2^\top \mathbf{r}) = 0, \end{aligned} \quad (3)$$

⁹Our model assumes a representative intermediary who accommodates all customer trades. In practice, such netting across currencies could also occur through interdealer trading.

¹⁰For example, normalizing f_n by the aggregate trading volume of the currency and then applying equation (1), would result in an incorrect aggregation.

¹¹Specifically, if $\mathbf{b}_1$ is doubled, $\beta_{n,1}$ in equation (1) is halved, causing q_1 to also halve, which leaves the objective function unchanged.

where $q_2 = \text{cov}(\mathbf{f}^\top \mathbf{r}, \mathbf{b}_2^\top \mathbf{r}) / \text{var}(\mathbf{b}_2^\top \mathbf{r})$.¹²

This sequential maximization procedure is similar to the standard principal component analysis (PCA) on *returns* alone, which is a common asset-pricing approach used to identify factors that maximally explain *unconditional risks* (Ross, 1976; Fama and French, 1993; Lustig, Roussanov, and Verdelhan, 2011).¹³ Our procedure extends the standard PCA framework by incorporating both trading and returns data to maximally explain *conditional trading-induced risks*. Appendix A.1 provides details on solving for these factors through eigenvalue decomposition. In theory, one can construct at most K factors, where K is the number of independent variations driving the flow $\mathbf{f}$ —mathematically, the rank of the matrix $\text{var}(\mathbf{f})$. Empirically, a small number of factors are typically sufficient to explain the majority of trading-induced risks.

Our procedure can also be interpreted as a risk-based extension of the standard PCA on *flows* alone, an intuitive approach for analyzing trading data. Specifically, if the returns of different currencies are i.i.d. (i.e., $\text{var}(\mathbf{r})$ is proportional to the identity matrix), our procedure becomes identical to the standard PCA on flows.¹⁴ Moreover, if the returns of different currencies are independent but each currency n has its own return volatility σ_n , our procedure reduces to the standard PCA on $\sigma_n f_n$, the risk-weighted flows.¹⁵ The most general form of the objective function (2) accommodates scenarios where different currencies can exhibit common variations in returns.

2.3 Price Sensitivity to Trading-Induced Risks

Having identified the traded risk factors, we now derive the price sensitivity to trading-induced risks of each factor through the portfolio optimization of a representative intermediary. Our model is kept deliberately simple to emphasize the relationship between trading and asset prices. We assume that the mass μ of intermediaries have CARA preference.¹⁶ In addition to risk aversion, the only type of friction that the model features is possible factor-specific frictions in accommodating risks, leading to possibly different factor-specific risk-aversion, denoted by γ_k for factor k . In practice, not all intermediaries may be willing to accommodate risks in every factor. If some intermediaries choose not to absorb risks of a

¹²Because the returns of different factors are uncorrelated by construction, the univariate beta defined here is equivalent to the multivariate beta.

¹³Specifically, the first factor $\mathbf{b}_1$ maximizes the variance of the factor return: $\text{var}(\mathbf{b}_1^\top \mathbf{r})$. The second factor $\mathbf{b}_2$, conditional on being uncorrelated with the first factor, i.e., $\text{cov}(\mathbf{b}_1^\top \mathbf{r}, \mathbf{b}_2^\top \mathbf{r}) = 0$, again aims to maximize the variance of the factor return: $\text{var}(\mathbf{b}_2^\top \mathbf{r})$, and so on.

¹⁴Specifically, (2) simplifies to $\max_{\{b_{1,1}, b_{2,1}, \dots, b_{N,1}\}} \text{var}(\sum_{n=1}^N f_n b_{n,1}) / (\sum_{n=1}^N b_{n,1}^2)$.

¹⁵Specifically, (2) simplifies to $\max_{\{g_1, g_2, \dots, g_N\}} \text{var}(\sum_{n=1}^N \sigma_n f_n g_n) / (\sum_{n=1}^N g_n^2)$, where g_n is defined as $\sigma_n b_{n,1}$.

¹⁶We can re-cast the absolute risk aversion as a function of wealth to mimic a CRRA preference.

certain factor k , this would manifest as a higher effective risk aversion, γ_k , in our model.

The traded risk factors in Section 2.2 are constructed using observed, equilibrium trading flows and returns. As such, we have identified the factors with the largest amount of trading-induced risks in equilibrium, which are priced partly due to changes in fundamentals (e.g., the arrival of news, learning from trades) and partly due to intermediaries being pushed against their risk-bearing capacity. Our goal is to compute the sensitivity of price change to uninformed *demand shocks*. To achieve this, we examine the price response of hypothetical and marginal demand shocks $\hat{f}_1, \dots, \hat{f}_N$, which occur between times 0 and 1 and are uninformed about currency prices at time 2. Due to intermediaries' limited risk-bearing capacity, the (percentage) price response of currency n at time 1 is

$$\Delta \hat{p}_n := \frac{P_n(\hat{f}_1, \dots, \hat{f}_N) - P_n(0, \dots, 0)}{P_n(0, \dots, 0)}, \quad (4)$$

where $P_n(\hat{f}_1, \dots, \hat{f}_N)$ is the exchange rate of currency n (measured as the number of USD per foreign currency) with demand shocks $\hat{f}_1, \hat{f}_2, \dots, \hat{f}_N$. Then, for factor k that holds $\$b_{n,k}$ of currency n against the USD, the price response is

$$\Delta p_k = \sum_{n=1}^N b_{n,k} \Delta \hat{p}_n. \quad (5)$$

The factor-level demand shock is aggregated in the same way as equation (1),

$$\hat{q}_k = \sum_{n=1}^N \beta_{n,k} \hat{f}_n. \quad (6)$$

The equilibrium price responses are such that each intermediary finds it optimal to buy $y_k = -\hat{q}_k/\mu$ dollars of factor k . For each additional dollar of factor k purchased, intermediaries bear an extra payoff risk of $\mathbf{b}_k^\top \mathbf{R}$ at time 2. This factor is bought at the adjusted price Δp_k at time 1, which is compounded to time 2 by multiplying it by the USD gross risk-free rate R_F . Hence, the representative intermediary's optimization problem reads

$$\{-\hat{q}_1/\mu, \dots, -\hat{q}_K/\mu\} = \arg \max_{\{y_1, \dots, y_K\}} \mathbb{E} \left[-\exp \left(-\sum_{k=1}^K \gamma_k y_k (\mathbf{b}_k^\top \mathbf{R} - R_F \Delta p_k) \right) \right]. \quad (7)$$

Applying the first-order condition to (7) and using the assumption that $\text{var}(\mathbf{r}) = \text{var}(\mathbf{R})$, Proposition 1 determines the equilibrium price response for each factor.

PROPOSITION 1 (Price sensitivity to trading-induced risks). Denoting $\lambda_k =$

$\gamma_k/(\mu R_F)$, the price response of factor k is

$$\Delta p_k = \lambda_k \hat{q}_k \text{var}(\mathbf{b}_k^\top \mathbf{r}). \quad (8)$$

The parameter λ_k is termed the “price sensitivity to trading-induced risks” of factor k , or simply “price sensitivity to risks.” By equation (8), we can express λ_k as follows:

$$\lambda_k = \frac{\Delta p_k}{\hat{q}_k \text{var}(\mathbf{b}_k^\top \mathbf{r})}. \quad (9)$$

Here, Δp_k represents the price response of factor k at time 1. The denominator, $\hat{q}_k \text{var}(\mathbf{b}_k^\top \mathbf{r})$, measures the change in the quantity of risk due to the marginal demand shock to the factor. Consequently, λ_k measures the price sensitivity to risks induced by demand shocks and captures the marginal risk–return tradeoff conditional on trading. This concept extends the canonical price of risk, which reflects the unconditional risk–return tradeoff. Note that in our simple model, λ_k is not a function of intermediaries’ pre-existing holdings at time 1, as we do not model nonlinear constraints (e.g., position limits).

We highlight three features of the price sensitivity to risks λ_k . First, because the traded risk factors have uncorrelated returns by construction, the equilibrium solution from (7) implies that demand shocks $\hat{q}_k$ affect only the price of factor k . In other words, demand shocks propagate across currencies through shared risk exposures, but not across factors. Appendix A.2 provides a proof. This result provides the theoretical foundation for estimating λ_k factor-by-factor without concern for cross-factor interactions. Second, λ_k is invariant to scaling or sign reversal of a factor. This highlights that, economically, $\lambda_k \approx \gamma_k/\mu$ reflects the intermediaries’ risk-bearing capacity, or their per-capita risk aversion to that factor. While λ_k is linked solely to γ_k and μ in our stylized model, the empirical estimate of λ_k may also reflect other constraints that intermediaries face when accommodating trading-induced risks for factor k . Calibrating to the estimated λ_k would require a more sophisticated macro-finance model that incorporates these additional features, which is beyond the scope of this paper. Third, the price sensitivity to risks is defined in terms of risks rather than securities, unlike the inverse demand elasticity $(\Delta P/P)/(\Delta Q/Q)$ commonly used in industrial organization. Although quantities of securities are readily observable, in markets where marginal agents optimize their portfolios to diversify risks, the quantities of risks are more relevant.

2.4 Demand Propagation Across Currencies

We now use the law of one price to connect factor-level price sensitivity with demand propagation across individual currencies. Consider the scenario where currency m experiences a \$1

demand shock (a one-dollar change to $\hat{f}_m$), while customers' demand for all other currencies remain constant. First, as in equation (6), this additional \$1 demand shock to currency m would increase the demand shock $\hat{q}_k$ to factor k by an amount $\beta_{m,k}$. Second, changes in factor- k demand shock affect its price by $\Delta p_k = \lambda_k \text{var}(\mathbf{b}_k^\top \mathbf{r})$ (Proposition 1). Finally, changes in factor- k price Δp_k affect currency- n price $\Delta \hat{p}_n$ through the law of one price, with the sensitivity being $\beta_{n,k}$. The partial derivative $\partial \Delta \hat{p}_n / \partial \hat{f}_m$ measures this demand propagation and is referred to as the “cross-multiplier.” Proposition 2 derives the model-implied cross-multiplier, and Appendix A.3 provides a proof.

PROPOSITION 2 (Demand propagation). *The cross-multiplier between currencies n and m is:*

$$\frac{\partial \Delta \hat{p}_n}{\partial \hat{f}_m} = \sum_{k=1}^K \frac{\partial \hat{q}_k}{\partial \hat{f}_m} \times \frac{\partial \Delta p_k}{\partial \hat{q}_k} \times \frac{\partial \Delta \hat{p}_n}{\partial \Delta p_k} = \sum_{k=1}^K \beta_{m,k} \times \lambda_k \text{var}(\mathbf{b}_k^\top \mathbf{r}) \times \beta_{n,k}. \quad (10)$$

The model-implied cross-multiplier has two features. First, the own-multiplier

$$\frac{\partial \Delta \hat{p}_n}{\partial \hat{f}_n} = \sum_{k=1}^K \beta_{n,k}^2 \times \lambda_k \text{var}(\mathbf{b}_k^\top \mathbf{r}) \quad (11)$$

is always positive as long as λ_k is positive. Positive λ_k indicates that intermediaries are averse to bearing trading-induced risks rather than risk-seeking. On the other hand, the cross-multiplier between two currencies could be negative, if the currencies have opposite signs of beta loading to a factor, which reflects complementarity. We return to this point empirically in Section 6.

Second, the cross-multiplier *as channeled through traded risk factors* is symmetric between any two currencies n and m , as shown by

$$\frac{\partial \Delta \hat{p}_n}{\partial \hat{f}_m} = \frac{\partial \Delta \hat{p}_m}{\partial \hat{f}_n}. \quad (12)$$

This symmetry arises because

$$\frac{\partial \hat{q}_k}{\partial \hat{f}_n} = \beta_{n,k} = \frac{\partial \Delta \hat{p}_n}{\partial \Delta p_k}. \quad (13)$$

The first equality, relating currency to factors in terms of quantity, follows from our portfolio theory (6), while the second equality, relating currency to factors in terms of price, results from the law of one price. Both relationships are governed by the beta of currency n to factor k , which gives rise to the symmetry.

3 Data

To identify traded risk factors, we need data on FX trading and returns. In this section, we outline the various data sources that we use.

3.1 Trading Data

Our FX trading data come from the CLS Group (CLS), which provides settlement services for FX trades conducted by its 72 settlement members, primarily large multinational banks.¹⁷ As the largest single source of FX execution data, CLS covers over 50% of global FX volumes.

We use daily aggregate FX order flow data from CLS, which includes the total value of buy and sell orders between Banks and their customers in 17 currencies from September 2012 to December 2023.¹⁸ The currencies in our sample are: U.S. dollar (USD), Australian dollar (AUD), Canadian dollar (CAD), Swiss frank (CHF), Danish kroner (DKK), Euro (EUR), British pound (GBP), Hong Kong dollar (HKD), Israeli shekel (ISL), Japanese yen (JPY), Korean won (KRW), Mexican peso (MXN), Norwegian kroner (NOK), New Zealand dollar (NZD), Swedish kroner (SEK), Singaporean dollar (SGD), and South African rand (ZAR). All trades involve Banks as one counterparty, where Banks include bank-affiliated dealers and hedge funds transacting through prime brokers. We interpret Banks' trading as representing the activities of the specialist intermediary in our model. Counterparties to Banks are grouped into three categories: Funds (e.g., mutual funds, pension funds, sovereign wealth funds), Non-bank Financials (e.g., insurance companies, clearing houses), and Corporates.

To measure the *total* FX risk borne by intermediaries, we are the first to jointly analyze the CLS flows data on FX spot (e.g. [Rinaldo and Somogyi, 2021](#); [Roussanov and Wang, 2023](#)) alongside data on FX forwards and swaps. Due to the pronounced negative correlation between flows into spot versus forward and swap, excluding either can underestimate the price sensitivity to risks (see Supplemental Appendix B). The CLS forward and swap data are organized by maturity buckets. We estimate FX spot exposure from these future-settled contracts by discounting the notional using forward rates.^{19,20} Aggregating across

¹⁷A list of settlement members can be found at <https://www.cls-group.com/communities/settlement-members/>.

¹⁸Both the number of currencies covered and the sample start date are constrained by CLS data availability.

¹⁹Conceptually, FX swaps should not expose intermediaries to currency risk, as the spot and forward legs offset each other in notional amounts. However, a small amount of currency risk remains after discounting the forward leg. Our results are effectively unchanged if swaps are excluded.

²⁰Specifically, we use the 1-week forward rate for contracts maturing in 1-7 days, the 1-month forward rate for contracts maturing in 8-35 days, the 3-month forward rate for contracts maturing in 36-95 days, and the 1-year forward rate for contracts maturing in more than 96 days. The choice for these rates reflects bucket maturity ranges and forward contract liquidity.

spot, forward, and swap, we construct the USD-valued total daily net customer inflow for each currency.

To align with our instruments, we analyze trading and return at the weekly frequency. Weekly flows are calculated by summing daily flows from Thursday to the following Wednesday. Our final trading data is a panel spanning 2012-09-06 to 2023-12-31, consisting of weekly net inflow into 16 non-USD currencies, measured in USD, across spot, forward, and swap transactions.

3.2 Return Data

We obtain the forward and spot data for the 16 non-USD currencies in our sample from Bloomberg. All prices are recorded at the London close. The CLS trading data also follow London business hours.

We define the weekly currency return as the result of borrowing USD at the US risk-free rate, converting to foreign currency at the spot exchange rate, earning the foreign risk-free rate, and converting back to USD at the future spot rate. For currency n from week t to $t + 1$, we define $r_{t+1,n} = s_{t+1,n} - s_{t,n} + i_{t,n} - i_{t,USD} - x_{t,n} = s_{t+1,n} - f_{t,n}$, where s is the log spot rate, f is the log forward rate, i is the net risk-free rate, and x is the deviation from the covered interest-rate parity (CIP). Exchange rates are defined as USD per one unit of foreign currency, so a higher s corresponds to USD depreciation. Our currency return includes the CIP deviation, $x_{t,n} = f_{t,n} - s_{t,n} - i_{t,USD} + i_{t,n}$, to more accurately reflect the actual return that intermediaries have when absorbing customer flows, including inventory costs from balance sheet constraints.

3.3 Other Data

We collect sovereign bond auction data to instrument for FX demand shocks. Specifically, we source announcement information on auctions of bonds with maturities of one year or longer from government websites in the U.S., Australia, Canada, France, Germany, Italy, Japan, and the U.K.

To construct excess returns in five non-FX asset classes, we use the following data. For credit default swaps (CDS), we obtain five Markit indices from Bloomberg (North America investment grade and high yield, Europe main and crossover, and Emerging Market), with returns defined from the seller’s perspective. For commodities, we use six Bloomberg commodity futures return indices (energy, grains, industrial metals, livestock, precious metal, and softs). For corporate bonds, we use four Bloomberg indices on U.S. corporate bonds by credit rating (Aa, A, Baa, high yield; excluding AAA to avoid collinearity with the risk-free

rate). For options, we calculate leverage-adjusted option portfolio returns on S&P 500 call and put prices from OptionMetrics, following [Constantinides, Jackwerth, and Savov \(2013\)](#). For US Treasury bonds, we use yields of the six maturity-sorted “Fama Bond Portfolios” from CRSP, excluding Treasury bills due to correlation with the risk-free rate. Finally, we use the 1-month U.S. Libor as a proxy for the risk-free rate.

The Bloomberg CDS data begin in 2007, OptionMetrics data end in December 2022, and all other asset classes data span January 2000 to December 2023.

4 Traded Risk Factors in FX

In this section, we identify the most traded FX factors from data. We first find that three risk factors account for most of the non-diversifiable risks induced by FX trading. We then interpret these factors as the Dollar, the Carry, and the Euro-Yen. Finally, we show that these factors cannot be obtained by the standard PCA on returns or flows alone.

4.1 Baseline Traded FX Factors

Our objective is to identify risk factors that capture the effect of FX trading on currency prices in the cross-section. To this end, we focus on factors that maximally explain trading-induced risks. Using the procedure detailed in [Section 2.2](#), we derive the traded FX factors from weekly net flows ($\mathbf{f}$) and log returns ($\mathbf{r}$) of 16 non-USD currencies.²¹ The three factors that explain the most amount of trading-induced risk are reported in [Table 1](#). Each column of [Table 1](#) represents a factor, and the component values are the currency weights in this factor. For example, in Factor 1, for every \$1 bought, \$0.15-worth of CAD and \$0.5-worth of EUR are sold.²² Because the identified risk factors are traded, they place greater weight on widely traded currencies. Notably, six developed economy currencies — AUD, CAD, CHF, EUR, GBP, and JPY — have consistently high weights across the top three factors; they are highlighted in red along with USD. Of the total trading-induced non-diversifiable risks, $\sum_{k=1}^K \text{var}(q_k) \text{var}(\mathbf{b}_k^\top \mathbf{r})$, the top three traded FX factors individually account for 65%, 16%, and 9%, respectively. Jointly, these three factors explain approximately 90% of the risks intermediaries bear when accommodating trading flows. The traded FX factors are stable over time. [Table SA3](#) in the Supplemental Appendix shows that the returns and flows of

²¹We use aggregate flows across all customer types to identify total trading-induced risks from the intermediaries’ perspective. Trades from different customers may carry different informational content but pose the same balance-sheet or inventory risk.

²²To facilitate comparison, we have scaled such that factor 1 has a weight of 1 for USD, factor 2 has all positive weights sum to 1 and all negative weights sum to -1, and factor 3 has a weight of -1 for JPY. Note that the portfolio weight of USD is the negative sum of the weights of all other currencies.

Table 1: **Top 3 Traded FX Factors**

Currency	Factor 1	Factor 2	Factor 3
AUD	-0.08	0.14	-0.08
CAD	-0.15	0.56	-0.87
CHF	-0.03	-0.07	-0.02
DKK	-0.01	0	0.02
EUR	-0.5	-0.43	1.16
GBP	-0.11	0.18	0.09
HKD	0	-0.01	0.02
ILS	0	0	0
JPY	-0.07	-0.49	-1
KRW	-0.01	0.01	-0.01
MXN	-0.01	0.02	-0.03
NOK	-0.01	0.02	-0.01
NZD	-0.01	0.02	-0.01
SEK	-0.01	0.01	-0.01
SGD	-0.01	0	0.02
ZAR	-0.01	0.01	-0.01
USD	1	0.03	0.74
Var explained	65%	16%	9%

Notes: This table presents the portfolio weights of the top 3 traded FX factors, constructed following the procedure in Section 2.2. The return and flow data for 16 non-USD currencies are weekly from September 2012 to December 2023. The portfolio weight of USD is computed as the negative sum of the weights of all other currencies.

factors recovered from the full sample are highly correlated with those recovered from the pre-2020 or the post-2020 subsamples. Indeed, the correlations are nearing 1 for the first factor and exceeding 0.8 for the other two.

4.2 Interpretation of Traded FX Factors

To better understand the risks captured, we conjecture and verify that the top three traded FX factors represent the Dollar, the Carry, and the Euro-Yen, respectively. Factor 1 in Table 1 assigns negative weights to all non-USD currencies, resembling the proverbial Dollar portfolio that shorts all non-USD currencies to bet on the USD exchange rate. We therefore propose a traded Dollar factor that goes long in USD and shorts the six most traded currencies (AUD, CAD, CHF, EUR, GBP, and JPY) in equal weights. Factor 2 has positive weights on high-interest-rate currencies (e.g., AUD, CAD, GBP) and negative weights on low-interest-rate currencies (e.g., JPY, CHF, EUR), consistent with the proverbial Carry

Table 2: **Correlation between Return and Flow for Baseline PC Factors versus for Proposed Economic Factors**

	Factor 1	Factor 2	Factor 3
Return	0.98	0.95	0.92
Flow	1.00	0.99	0.95
Var explained by Economic Factors	63%	15%	8%

Notes: This table shows the correlation between return and flow for the baseline traded FX factors in Table 1 (“PC Factors”) and for the traded FX factors constructed from the proposed factor weights of the Dollar, the Carry, and the Euro-Yen (“Economic Factors”). It also shows the fraction of trading-induced risks explained by the Economic Factors.

portfolio that exploits violations of uncovered interest-rate parity (UIP). We propose a traded Carry factor that goes long in AUD, CAD, and GBP, and shorts CHF, EUR, and JPY, all in equal weights. Factor 3 features a large positive weight on EUR and a large negative weight on JPY, motivating a traded Euro-Yen factor that goes long in EUR and shorts JPY in equal weights. The rationale is that, because EUR and JPY are traded in the same direction in both Dollar and Carry factors, these factors do not capture the bilateral trading flows between the Euro area and Japan, two of the world’s largest economies.

These proposed factors are economically meaningful but may be correlated. To address this, we apply the procedure described in Section 2.2 to orthogonalize them. In particular, this process transforms the proposed EUR-JPY pair (long EUR, short JPY) into the Euro-Yen factor, which is uncorrelated with the Dollar and Carry factors. In other words, the Euro-Yen factor captures the portion of non-diversifiable risk that intermediaries bear when absorbing EUR-JPY pair trading, after hedging out exposures to the Dollar and Carry factors. Empirically, for every dollar traded in the EUR-JPY pair, 13% of the risk is attributed to the Dollar factor, 25% to the Carry factor, and 62% to the Euro-Yen factor.

The data support our interpretation of the traded FX factors. Table 2 shows the correlation between returns and flows of the baseline factors (“PC Factors”) from Table 1 and returns and flows of the factors constructed from the proposed Dollar, Carry, and Euro-Yen weights (“Economic Factors”). The correlations are nearly 1 for both returns and flows across all three factors. Together, the three Economic Factors explain about 86% of trading-induced non-diversifiable risks, closely matching the risks accounted for by the PC Factors. Given this striking similarity and to avoid potential in-sample overfitting concerns with PC Factors, we focus on analyzing the more interpretable Economic Factors for the remainder

of the paper.

Panel (a) of Figure 1 plots the cumulative trading flows from customers to the three traded FX factors.²³ During our sample period, customers purchased approximately \$1 trillion of the Dollar factor from intermediaries, primarily after the 2020 COVID crisis. This provision of USD by intermediaries likely reflects USD deposits or wholesale funding made available by (dealer-affiliated) banks (Du and Huber, 2024), as some intermediaries, especially dealers, may not be able to maintain a sustained inventory imbalance. For the Carry factors, customers initially refrained from large directional bets but began selling off the Carry factor post-2022. As a result, intermediaries including dealers and hedge funds accumulated \$0.8 trillion in Carry trade exposure between 2012 and 2023. Finally, customers sold the Euro-Yen factor up until the 2020 COVID crisis, after which they started repurchasing some, but not all, positions. This left the intermediaries with a net positive position in the Euro-Yen factor throughout the sample period. As JPY acts as a “funding currency” (negative weight) in both the Carry and Euro-Yen factors, our analysis highlights that the unwinding of intermediaries’ short JPY positions cannot solely be attributed to the Carry trade.

Panel (b) of Figure 1 plots the cumulative returns of the three factors over our sample period. We observe that all three factors enjoy positive returns, including the Euro-Yen factor. We formally investigate the unconditional risk premium of these factors in Section 5.1.

4.3 Standard PCA on Returns or Flows Fails to Identify Traded Risk Factors

We demonstrate that a standard PCA applied solely to returns or flows fails to identify the traded FX factors. The results underscore the empirical value of using our approach to jointly analyze returns and flows.

The first three columns of Table 3 show the portfolio weights for the first three principal components of a standard PCA applied to returns.²⁴ The first factor resembles a Dollar factor, with negative loadings on all currencies. The second factor assigns large positive weights to some high-interest-rate currencies such as ZAR and MXN, and large negative weights to some low-interest-rate currencies like CHF, JPY, and EUR. However, it also assigns very small positive weights to other high-interest-rate currencies like AUD and NZD and even a negative weight to GBP and NOK.²⁵ The third factor lacks a clear economic

²³Figure SA2 in the Supplemental Appendix provides a breakdown of factor flows by customer type.

²⁴The eigenvectors from a return PCA represent individual currencies’ betas to the factors. We convert these betas into portfolio weights using the pseudoinverse of the beta matrix, following the factor-mimicking portfolio approach of Fama and MacBeth (1973).

²⁵Lustig, Roussanov, and Verdelhan (2011) identify the Carry factor from the second principal component

Figure 1: **Cumulative Flow and Return of Top 3 Traded FX Factors**

(a) **Cumulative Flow**

(b) **Cumulative Return**

Notes: This figure displays the cumulative flows and returns of the top three traded FX factors between September 2012 and December 2023. Flows are measured from the perspective of customer purchases (intermediary sales). For instance, the figure indicates that customers bought approximately \$1 trillion of the Dollar factor from intermediaries during this period.

interpretation. In contrast, our approach of jointly analyzing flows and returns yields a significant traded risk factor that is unambiguously the Carry and reveals an economically meaningful Euro-Yen factor.

The next three columns of Table 3 report the portfolio weights for the first three principal components of a standard PCA applied to flows. The resulting portfolios from this approach primarily allocate weight to a single major currency. For instance, the first factor assigns a portfolio weight of -1 to EUR and 0 to all other non-USD currencies, reflecting after sorting currencies into six portfolios based on interest rate levels.

Table 3: **Top 3 PCs from FX Returns or Flows**

Currency	Return PCA			Flow PCA		
	PC 1	PC 2	PC 3	PC 1	PC 2	PC 3
AUD	-0.08	0.04	0.27	-0.03	0.03	0.12
CAD	-0.05	0.05	0.32	-0.04	1	-0.06
CHF	-0.05	-0.21	-0.51	-0.01	-0.02	-0.06
DKK	-0.06	-0.15	-0.12	0	0	0.01
EUR	-0.06	-0.15	-0.13	-1	-0.03	0.03
GBP	-0.07	-0.08	0.47	-0.02	-0.01	0.26
HKD	0	0	0	0	-0.02	0
ILS	-0.04	-0.03	0.24	0	-0.01	0
JPY	-0.03	-0.17	-1	-0.04	-0.06	-0.95
KRW	-0.06	0.02	-0.15	0	0.01	0
MXN	-0.08	0.22	0.71	-0.01	0.01	0
NOK	-0.1	-0.05	0.72	0	0.01	0.01
NZD	-0.08	0.01	0.13	-0.01	0.01	0.01
SEK	-0.08	-0.13	0.22	0.01	0	0
SGD	-0.04	-0.03	-0.12	-0.01	-0.01	0.01
ZAR	-0.11	0.29	-1.35	-0.01	0	0.01
USD	1	0.37	0.29	1.17	-0.92	0.62

Notes: The first three columns display the portfolio weights for the first three principal components from a return PCA, while the second three columns show those from a flow PCA. The analysis uses weekly data for 16 non-USD currencies spanning September 2012 to December 2023. The USD portfolio weight is calculated as the negative sum of the weights of all other currencies.

that EUR/USD is the most actively traded pair. The second and third principal components correspond to the CAD/USD and JPY/USD pairs, respectively. This outcome occurs because the flow PCA identifies portfolios based solely on the largest trading volumes, entirely overlooking the strong factor structure in returns.

5 Pricing Properties of Traded FX Factors

In this section, we study the traded FX factors' unconditional risk premium and their price sensitivity to trading-induced risks.

5.1 Unconditional Risk Premium

Panel A of Table 4 reports the annualized mean returns and Sharpe ratios of the three traded FX factors based on weekly returns from September 2012 to December 2023. Notably, the

Table 4: **Unconditional Risk Premium**

Panel A: Sep 2012 to Dec 2023			
	Dollar	Carry	Euro-Yen
Mean return (annualized %)	2.38	2.15	5.26
Sharpe ratio (annualized)	0.35	0.26	0.56
Fama-MacBeth premium (annualized %)	2.42	3.34	3.58
t-stats	(1.15)	(1.22)	(1.12)
Panel B: Jan 2000 to Dec 2023			
	Dollar	Carry	Euro-Yen
Mean return (annualized %)	-0.16	2.09	1.99
Sharpe ratio (annualized)	-0.02	0.23	0.20
Fama-MacBeth premium (annualized %)	-0.07	3.02	1.00
t-stats	(-0.04)	(1.41)	(0.40)

Notes: This table presents the annualized mean return and Sharpe ratio of the three traded FX factors. Additionally, it reports the Fama-MacBeth factor premium along with t-statistics calculated using Shanken-corrected standard errors. Panel A is based on weekly returns from September 2012 to December 2023, while Panel B uses weekly returns from January 2000 to December 2023.

newly proposed Euro-Yen factor achieves an annualized return exceeding 5% and a Sharpe ratio of 0.56, both meaningfully higher than those of the other two factors. To evaluate the cross-sectional pricing power of these factors, we estimate the Fama-MacBeth factor premia.²⁶ The Fama-MacBeth premia of the three factors are similar to their mean returns estimated from the time series, though we caution that the estimated Fama-MacBeth premia are not statistically significant, which may partly reflect that the portfolios are static and not conditionally rebalanced as in [Lustig, Roussanov, and Verdelhan \(2011\)](#).

Our sample period begins in September 2012 due to the availability of CLS data. To further explore unconditional risk premia, we extend the sample to start in 2000 (introduction of the Euro) and report the results in Panel B. In this longer sample, the Euro-Yen factor exhibits a time-series mean return and Sharpe ratio comparable to the Carry factor. In the cross-section, the Carry factor demonstrates considerably stronger pricing power than the other two factors.

²⁶We follow the Fama-MacBeth two-step procedure: first, time-series regressions of each currency's return on factor returns estimate betas; second, cross-sectional regressions of average currency returns on these betas (excluding the constant) recover the factor premium. Standard errors are corrected following [Shanken \(1992\)](#).

5.2 Price Sensitivity to Trading-Induced Risks

We aim to estimate λ_k , the price sensitivity to trading-induced risks of traded FX factor k in equation (8). Because the traded FX factors are constructed to have uncorrelated returns, the theoretical foundation in Proposition 1 ensures that λ_k can be estimated factor-by-factor without concern for cross-factor substitution. However, for each factor, we must instrument for the unobserved demand shocks that are unrelated to changes in fundamentals. Specifically, we regress each factor’s risk-adjusted returns²⁷ on its instrumented weekly flows, $\hat{q}_{k,t}$:

$$r_{k,t}/\text{var}(r_{k,t}) = \lambda_k \hat{q}_{k,t} + \epsilon_{k,t}, \text{ where} \quad (14)$$

$$q_{k,t} = \theta_k z_{k,t} + e_{k,t}, \quad (15)$$

$$\text{cov}(z_{k,t}, \epsilon_{k,t}) = 0. \quad (16)$$

The instruments (z_k) for the observed factor flows (q_k) must be both relevant (equation (15)) and valid (equation (16)). We propose sovereign bond auction *announcements* as instruments.²⁸ Government entities, such as the U.S. Treasury, periodically auction off long-term debt obligations, e.g., U.S. Treasury notes and bonds. Foreign investors actively participate in these auctions; for instance, they directly purchased on average 14% of U.S. Treasury notes and bonds sold at auctions between September 2012 and December 2023.²⁹ When auctions are announced about a week in advance, these announcements can prompt foreign investors to exchange domestic currencies for local currencies, making these instruments relevant.

We also argue that the instruments are valid. First, auction announcements are plausibly exogenous to FX trading because auctions follow strong fiscal cyclicalities and are largely predetermined. For example, the U.S. Treasury Borrowing Advisory Committee (TBAC) issues two-quarter-ahead recommendations on debt issuance for upcoming auctions. The subsequent announcements and the eventual issuance of long-term debt (maturities of longer than a year) rarely deviate from these recommendations (Rigon, 2024).³⁰ Although these

²⁷Each factor’s weekly observed return $r_{k,t}$ is normalized by its annualized return variance, $\text{var}(r_{k,t})$, so the regression coefficient estimates the price sensitivity to risk λ_k , as defined in Proposition 1. Technically, theory implies that the variance should be measured in the absence of demand shocks. In practice, we use realized variance because the demand shocks we study are small in magnitude and likely contribute little to the overall return variance.

²⁸We focus on auctions for securities with maturities of longer than a year, as short-term securities are typically bought by domestic investors such as money market funds.

²⁹This 14% excludes foreign purchases made indirectly through U.S. investment funds and dealers, so the actual figure may be higher.

³⁰Similarly, Germany’s Finance Agency releases an annual auction calendar each December, specifying target amounts for each auction.

auction-induced demands are predictable, they can still move prices when they materialize. Theoretically, sophisticated investors do not find it optimal to front-run the entire expected demand (Vayanos, 2021); empirically, demand shocks generated by anticipate stock dividend payments nonetheless move stock prices (Hartzmark and Solomon, 2024).

Second, auction announcements plausibly satisfy the exclusion restriction that their effect on exchange rates arises solely through FX trading. Because auctions are heavily forward-guided, announcements likely contain limited new information that would affect fundamentals ($\epsilon_{k,t}$). Another concern is that auction announcements might induce excess bond trading, affecting bond prices and spilling over to FX. However, empirically, Wachtel and Young (1990) find that while Treasury auction *results* move bond yield, the week-ahead *announcements* have no detectable effect. Thus, any impact on FX is likely driven solely by announcement-induced FX demand shocks.

Finally, the behavior of asset prices provides a test for the validity of our instrument. As discussed in Section 2, valid demand shocks move currency prices initially (at time 1), but these price effects should eventually revert (at time 2). In contrast, if the considered demand shocks contained new information, the resulting price response would be permanent and not revert. Empirically, Figure SA3 in the Supplemental Appendix shows that the contemporaneous price responses of all three factors fully revert within a month.

As the traded FX factors place weights on multiple currencies, we consider sovereign auction announcements from a panel of countries. Specifically, U.S. Treasury auction announcements instrument demand shocks to the Dollar factor; Australian, Canadian, British, and Japanese government bond auction announcements instrument shocks to the Carry factor, and Euro-Area government bond auctions (aggregating German, French, and Italian auctions) instrument for the Euro-Yen factor. For each factor, we aggregate the offered amount across all announcements in a week, consistent with FX trading flows.³¹ Finally, we remove any linear trend in auction sizes over time.

Table 5 presents the λ_k estimation results for the Dollar, Carry, and Euro-Yen factors. For all three factors, the estimated price sensitivity to trading-induced risks is positive and statistically significant. Recall that the regression (14) normalizes each factor’s return by its variance. As a result, the estimated λ_k captures the price response to one unit of *risk* induced by \$1 billion of factor flow and is directly comparable across factors. Both OLS and IV estimates show that the price sensitivity to risks is the smallest for the Dollar, higher for the Carry, and highest for the Euro-Yen. This indicates that intermediaries bear marginal

³¹To instrument for factor flows in week t , we use same-week announcements for the Dollar and Carry factors and announcements from weeks $t - 1$ and t for the Euro-Yen factor. This longer window accounts for potential delays in auction-induced currency conversion, as Germany, France, and Italy do not allow direct bids from foreign investors.

Table 5: **Estimated Price Sensitivity to Trading-Induced Risks**

	Dollar		Carry		Euro-Yen	
	OLS (1)	IV (2)	OLS (3)	IV (4)	OLS (5)	IV (6)
Factor flow	0.072*** (0.009)	0.107*** (0.037)	0.132*** (0.018)	0.138** (0.064)	0.139*** (0.021)	0.335* (0.195)
Response per \$B (bps)	3.4	5.0	8.9	9.3	12.2	29.3
1st stage F-stat		24.8		6.5		3.8
Anderson-Rubin CI				(0.01, 2.39)		(0.09, 1.91)
Observations	590	386	590	228	590	560

Notes: This table presents the λ_k estimation results for the Dollar, Carry, and Euro-Yen factors, based on regression (14). The response of factor prices to demand shocks, measured per billion dollars, is calculated as the product of λ_k and the annualized return variance. The IV regressions report the first-stage heteroscedasticity and autocorrelation consistent (HAC) effective F-statistics and the Anderson-Rubin confidence intervals at the 90% confidence level. The estimation period spans September 2012 to December 2023, excluding the first half of 2020. Newey-West standard errors are reported in parentheses, where the bandwidth is chosen by the Newey and West (1994) selection procedure. * $p < .1$; ** $p < .05$; *** $p < .01$.

risks most effectively in the Dollar factor, with their risk-bearing capacity progressively lower for the Carry and the Euro-Yen. Viewed through Proposition 1, the cross-factor variation in price sensitivity to risks may reflect differences in available arbitrage capital across risk factors, with lesser-known factors like Euro-Yen attracting less arbitrage capital. Indeed, the annualized volatility of trading flows absorbed by intermediaries is highest for the Dollar factor (\$85 billion), followed by the Carry factor (\$ 34 billion), and lowest for the Euro-Yen factor (\$22 billion). The OLS estimates are slightly smaller than the IV estimates, reflecting the instrument’s role in mitigating bias from the correlation between information-driven price changes $\epsilon_{k,t}$ and contemporaneous customer flows q_k . This correlation is negative, likely because customers trade against fundamentals: they buy when news causes a currency to depreciate and sell when it appreciates. Such behavior is consistent with the profitability of momentum strategies in FX (Menkhoff, Sarno, Schmeling, and Schrimpf, 2012).³²

To compare the magnitude of our estimated price sensitivity to risks with the literature, we multiply each factor’s λ_k by its return variance to calculate the factor-level price response per billion of demand shocks, as shown in the second row of Table 5. A \$1 billion demand shock increases the prices of the Dollar, Carry, and Euro-Yen factors by 5, 9, and 29 basis

³²In a rational market, prices would adjust to fundamental news without trading (Milgrom and Stokey, 1982). However, when customers buy in response to negative fundamental news, prices under-react, leading to subsequent price drift and generating momentum.

points, respectively.³³ These price responses are large compared to U.S. equities, where a \$1 billion demand shock to the entire U.S. stock market raises the aggregate price by about 1.7 bps (Gabaix and Koijen, 2021).³⁴ We think that the supply of FX arbitrage capital is likely limited due to the specialized nature of the FX market, where only sophisticated participants like bank dealers and hedge funds absorb demand shocks.³⁵ This may seem counterintuitive given the large turnover in FX, but up to 75% of trades occur between intermediaries (BIS, 2022), suggesting that the arbitrage capital available to absorb shocks is much smaller than the total turnover.³⁶

Because our estimates are obtained through IV analysis, which reflect the local average treatment effect, we caution against extrapolating our estimates to much larger demand shocks, such as quantitative easing. Nevertheless, our results can be informative about the effect of larger interventions. Specifically, as our estimates are based on relatively small, high-frequency shocks, intermediaries likely absorb these shocks with a risk-bearing capacity that is fixed in the short-run. If there are larger shocks, however, intermediaries may expand their capacity (e.g., bank-affiliated dealers could tap into the banks’ broader balance sheets). Such global re-optimization likely leads to a smaller average price response per unit of risk, as the price impact function may be concave (Hasbrouck, 1991; Chaudhry and Li, 2025). Our estimates thus form an upper bound for the price impact of larger shocks.

Additionally, because the price impacts of these factor-level demand shocks revert within a month, Appendix B derives an expression for the share of return variance contributed by trading volatilities over different horizons. Applying this formula across the three factors, we find that flows account for about 10–35% of variance at the 1-week horizon, 5–15% at one month, and fade quickly thereafter. These results confirm that demand shocks are a meaningful yet short-lived source of return volatility.

Finally, the precision of IV estimation depends on the strength of the instrument. The heteroscedasticity and autocorrelation consistent (HAC) effective F-statistics for the Dollar, the Carry, and the Euro-Yen factors are 24.8, 6.5, and 3.8, respectively. The effective F-

³³In a dynamic setting, the persistence of demand shocks can influence price response, as intermediaries anticipate future demand (e.g., Campbell and Kyle, 1993; Wang, 1993; Jansen, Li, and Schmid, 2024). Our estimates reflect the average level of persistence over the sample period.

³⁴Gabaix and Koijen (2021) find that a 1% greater demand shock to the entire US stock market increases price by 5%. Given an average market capitalization of \$31.7 trillion between 2012 and 2022, a \$1 billion demand shock raises the price of the market factor by 1.7 bps over our sample period.

³⁵The limited FX arbitrage capital may also reflect slow-moving capital and the fact that our price sensitivity to risks is estimated based on a weekly horizon, shorter than the monthly or quarterly horizons typically considered in the literature. Asset markets tend to be more inelastic over shorter horizons as long-term investors are slower to react to price changes and provide arbitrage capital (Duffie, 2010).

³⁶Of the FX trades accounted for in the BIS Triennial Central Bank Survey, 46% are between reporting dealers, 22% with non-reporting dealers, and 7% with hedge funds, all of which are intermediaries in our model and captured in Banks in the data.

statistics for the Carry and the Euro-Yen are below the rule-of-the-thumb threshold of 10. To assess the implications of potentially weak instruments on IV inference, we compute the Anderson-Rubin confidence interval, which has the correct coverage regardless of the strength of the instrument (Andrews, Stock, and Sun, 2019). For both the Carry and the Euro-Yen, the Anderson-Rubin confidence interval is bounded away from zero, but is very wide in the positive direction. In other words, we are reasonably confident that the price sensitivity to risks is not zero but much less certain that the true value is not larger. A larger estimate would mean an even greater price sensitivity to risk.

5.3 Time-Varying λ and the Role of Risk

Our representative intermediary framework posits that price responses to trading stem from intermediaries’ sensitivity to risk. In the previous subsection, we discussed patterns in the estimated λ consistent with this view — for instance, specialization may limit arbitrage capital and risk-bearing capacity, resulting in larger price responses. In this subsection, we seek more direct evidence that risk drives observed price responses to trading. Specifically, we examine whether λ depends on time-varying wealth or constraints that alter intermediaries’ risk-return trade-off.

We consider two proxies. First, we use intermediary equity returns to capture intermediaries’ wealth.³⁷ Second, we use deviations from covered interest-rate parity (CIP) to capture intermediaries’ constraints, as such deviations indicate intermediaries’ inability to exploit known profitable trades.³⁸

Table 6 presents potential determinants of the Dollar factor’s weekly return. We emphasize the state-dependency of the Dollar factor’s λ , as the Dollar is the most traded FX factor and its flow instrument exhibits the highest statistical power. Column (1) suggests that the Dollar factor reflects variations in intermediary equity returns. However, Column (2) clarifies that intermediary equity returns do not directly affect the Dollar’s return. Instead, they influence λ , consistent with a risk-based view of price response: as intermediaries’ wealth increases, their effective risk aversion decreases, reducing the price response to absorbing demand shocks (instrumented using U.S. Treasury auction announcements). This state-dependent response is driven specifically by intermediaries’ wealth, as Columns (3) and (4) show that broader stock market returns have no comparable effect on λ . Concep-

³⁷Following He, Kelly, and Manela (2017), we construct the value-weighted weekly return of primary dealers’ bank holding companies. This series is highly correlated (0.95) with the KBW NASDAQ bank index over our sample period and is equivalent to the intermediary capital ratio shock (0.98 correlation) in He, Kelly, and Manela (2017).

³⁸We calculate the weekly average cross-currency basis using the AUD-JPY currency pair and 3-month IBOR.

Table 6: **Time-Varying λ for the Dollar Factor**

	Weekly Return of Dollar Factor					
	(1)	(2)	(3)	(4)	(5)	(6)
Intermed. ret	-0.490*** (0.119)	-0.109 (0.204)				
Flow $\times$ Intermed. ret		-0.091*** (0.033)				
S&P ret			-0.148 (0.096)	-0.077 (0.314)		
Flow $\times$ S&P ret				0.006 (0.074)		
CIP deviation					0.081 (0.060)	0.182 (0.177)
Flow $\times$ CIP deviation						0.063 (0.129)
Factor flow		0.096*** (0.037)		0.106*** (0.040)		0.160* (0.093)
Observations	559	385	559	385	559	385

Notes: This table reports the IV-estimated time-varying λ for the Dollar factor. “Intermed. ret” is the value-weighted weekly equity return of primary dealers’ bank holding company. “S&P ret” is the weekly return of the S&P 500 index. “CIP deviation” is measured by the weekly average AUD-JPY 3-month IBOR cross-currency basis. All three variables are demeaned and standardized. All factor flows are instrumented with U.S. Treasury auction announcements. Newey-West standard errors are reported in parentheses, where the bandwidth is chosen by the [Newey and West \(1994\)](#) selection procedure. * $p < .1$; ** $p < .05$; *** $p < .01$.

tually, intermediaries’ constraints may also affect price response: when constraints prevent intermediaries from fully exploiting profitable investment opportunities, they become more selective, leading to higher effective risk aversion and lower risk-bearing capacity. Empirically, the effects of such constraints, proxied by CIP deviations, are directionally consistent with the risk-return trade-off but, as shown in Column (6), not statistically significant.

6 Demand Propagation Across Currencies and Asset Classes

In this section, we use the traded FX factors’ estimated price sensitivity to risks to study the propagation of demand shocks among currencies and asset classes. We quantify demand propagation with cross-multipliers: the effect of a shock to demand for one asset on the price of another, holding all other demand constant.

Figure 2: **Decomposition of Currency Returns Explained by Traded FX Factors**

Notes: This figure plots the R^2 of regressing currency-level returns against the returns of the Dollar, the Carry, and the Euro-Yen factors in the time series. It plots the marginal R^2 values attributed to each factor and labels the total R^2 . The positive and negative signs illustrate the direction of the beta loadings.

6.1 Demand Propagation Across Currencies

For a traded FX factor to affect currency-level cross-multipliers, the currencies must load on the factor. Figure 2 demonstrates the relevance of the traded FX factors in explaining individual currency returns. Regressing currency-level returns on the returns of the Dollar, the Carry, and the Euro-Yen factors in the time series, we plot the marginal R^2 attributed to each factor, which are additive because the factor returns are orthogonal by construction. The positive and negative signs in the plot indicate the direction of each currency's beta loading on each factor. Together, the three factors explain between 69% and 94% of individual currency returns.

The decomposition in Figure 2 provides a framework to analyze the risk implied in demand shocks. For instance, when a customer buys \$1 of AUD from intermediaries, Figure 2 shows that intermediaries attribute 60% of the total risk to the Dollar factor, 10% each to the Carry and Euro-Yen factors, and 20% to idiosyncratic risk unexplained by the three factors. The direction of factor loadings further reveals that intermediaries perceive the customer's \$1 purchase (and their \$1 sale) of AUD as the customer selling the Dollar and Euro-Yen factors while buying the Carry factor.

Combining the information in Figure 2 with the IV estimated price sensitivity to risks λ_k , we compute the cross-currency multipliers according to Proposition 2 and report the results in Table 7. For clarity, we have arranged the six major currencies (AUD, CAD, GBP, CHF, EUR, JPY) in the upper left quadrant, followed by the other ten currencies in the sample. Each entry shows the price response in one row (column) currency, in basis points, to a \$1

Table 7: Demand Propagation Across Currencies Through the Three Most Traded FX Factors

	AUD	CAD	GBP	CHF	EUR	JPY	DKK	HKD	ILS	KRW	MXN	NOK	NZD	SEK	SGD	ZAR

NOK												11.1	9.4	8.2	4.3	10.5
NZD													9.1	5.7	3.9	9.6
SEK														7.7	3.1	6.8
SGD															1.9	4.1
ZAR																10.5

Notes: This table uses Proposition 2, the estimated factor-level price sensitivity to risks λ_k from Table 5, and the beta loadings of currencies to factors (signs illustrated in Figure 2) to compute currency-level cross-multiplier. Each entry represents the percentage price change in bps of a row (column) currency, as induced by a \$1 billion demand shock to a column (row) currency, holding the demand in all other currencies equal. As noted after Proposition 2, the model-implied cross-multiplier is symmetric, so we report only the upper half.

billion demand shock to the corresponding column (row) currency. For instance, the entry of 7.9 in the first row and second column indicates that a \$1 billion demand shock to the CAD (AUD) raises the price of AUD (CAD) by 7.9 bps (in percentage terms), holding the demand for all other currencies equal. Because the model-implied cross-multiplier is symmetric, we report only the upper half. The diagonal entries represent each currency’s own multiplier. As discussed in relation to the literature, the diagonal multipliers in Table 7 reflect price responses due to the three most traded FX factors; they exclude price impacts arising from changes in a currency’s idiosyncratic risk.

Table 7 reveals several interesting patterns of cross-currency multipliers. First, all entries are positive. This is because all currencies load on the Dollar factor in the same direction, which is the most traded risk factor in the cross-section. Second, the cross-multiplier between currencies on the long leg of the Carry trade (e.g., AUD, CAD, GBP) and those on the short leg (e.g., CHF, EUR, JPY) is generally smaller. The modest cross-multipliers reflect opposite beta loadings with respect to the Carry factor, which makes currencies in one group effective hedges for the Carry risk exposure of the other group. In short, these two groups are “complements” in their exposure to the Carry risk factor. Third, we note that although EUR and JPY are both low-interest-rate currencies, we estimate a rather small cross-multiplier because the two currencies are on the opposite side of the Euro-Yen factor. This result suggests that EUR and JPY are not entirely substitutable.

Moreover, although we analyze traded FX factors constructed based on the six major currencies and USD, we recover meaningful cross-multiplier in other currencies due to these currencies’ loadings on the three traded FX factors. Finally, as a sanity check of our methodology, we examine the cross-multiplier for HKD, a currency pegged to USD within a narrow band of 1%. While we do not use this pegged information in our estimation, the estimated cross-multipliers in the entire column and row associated with HKD are close to zero. This minimal impact reflects the nature of a pegged currency: its own demand shocks have negligible risk implications for other currencies, and its exchange rate relative to USD is largely unaffected by demand shocks to other currencies.

6.2 Demand Propagation Across Asset Classes

If other asset classes load on the traded FX factors, demand shocks can propagate through shared FX exposures. We analyze five non-FX asset classes: credit default swap (CDS), commodities (Comm), corporate bonds (CorpBond), options (Opt), and US Treasury bonds (UST).³⁹ Similar to Figure 2, we regress the monthly excess returns of each asset class

³⁹We exclude equities because [Haddad and Muir \(2021\)](#) show that intermediation in equities differs considerably from FX, suggesting different marginal investors. While traded FX factors may partially explain

Figure 3: **Decomposition of Asset-Class Returns Explained by Traded FX Factors**

Notes: This figure plots the R^2 of regressing individual asset's monthly excess returns against the returns of the Dollar, the Carry, and the Euro-Yen factors in the time series. It plots the marginal R^2 values attributed to each factor and labels the total R^2 . The positive and negative signs illustrate the direction of the beta loadings. The estimation period is from 2000-02 to 2023-12. The returns from CDS are available starting in 2007-04. The returns from Opt end in 2022-12.

from 2000-02 to 2023-12 on the Dollar, Carry, and Euro-Yen returns, and present the R^2 decomposition in Figure 3.^{40,41}

The three traded FX factors jointly explain between 15% (commodities) and 37% (corporate bonds) of the returns in the five non-FX asset classes we examine. The high explanatory power of traded FX factors is not an artifact of crisis-period comovements. As shown in Figure SA4 of the Supplemental Appendix, results based on returns excluding the 2007–09 Financial Crisis and the COVID-19 period are largely similar. Interestingly, while the Dollar factor is statistically significant across all five asset classes, it is least important in explaining the return of U.S. Treasury bonds (Treasurys).⁴² Moreover, while all other asset classes load positively on the Carry factor, Treasurys load negatively. This contrast suggests that large shocks to the Carry factor could drive divergent price movements between Treasurys and other assets. Finally, while the Euro-Yen factor is less prominent in non-FX asset classes, it

equities returns, their price sensitivities are likely different in equities.

⁴⁰We construct the return of each asset class as the equal-weighted average return of all available portfolios; see also Section 3.3.

⁴¹By construction, the correlation among weekly factor returns is zero. The correlation among monthly factor returns is close to zero. We report the incremental R^2 by adding the factors sequentially in the order of the Dollar, the Carry, and the Euro-Yen.

⁴²One possible reason for this attenuated connection is that foreign investors hedge a substantial amount of the USD FX risks associated with their securities holdings, especially bonds (Du and Huber, 2024).

Table 8: **Demand Propagation Across Asset Classes Through Shared FX Risks**

	CDS	Comm	CorpBond	Opt	UST
CDS	2.4	3.5	3.2	4.7	-0.5
Comm		8.9	6.0	7.7	0.7
CorpBond			4.8	6.5	-0.2
Opt				9.3	-0.6
UST					0.7

Notes: This table uses Proposition 2, the estimated factor-level price sensitivity to risks λ_k from Table 5, and the beta loadings of assets to factors (signs illustrated in Figure 3) to compute asset-level cross-multiplier. Each entry represents the percentage price change in bps of a row (column) asset, as induced by a \$1 billion demand shock to a column (row) asset, holding the demand for all other assets equal. As noted after Proposition 2, the model-implied cross-multiplier is symmetric, so we report only the upper half.

explains a non-negligible fraction of returns in corporate bonds.

Similar to Table 7, we report cross-multipliers between asset classes in Table 8.⁴³ Examining the last column of Table 8, we recover two salient features of Treasuries while using only assets’ factor loadings and factors’ price sensitivity to risks. First, the price response to a demand shock is smallest for Treasuries, corroborating the observation that the Treasury market is deep and liquid. Second, Treasuries uniquely exhibit negative cross-multipliers with most other asset classes. A \$1 billion demand shock to Treasuries raises their price but depresses the price of other assets, reflecting Treasuries’ “safe haven” property. Our estimation captures this behavior because only Treasuries load negatively on the commonly priced Carry factor, making them an effective hedge against other asset classes during shifts between “risk-on” and “risk-off” regimes.

We raise two cautions in interpreting our estimated cross-asset multipliers. First, our estimates capture only demand propagation across asset classes through exposure to the three traded FX factors. They may not represent the total price response to a \$1 demand shock to an asset, as these assets may also be exposed to other shared risks that we do not capture. Second, by using λ_k from the traded FX factors to inform multipliers in other asset markets, our analysis implicitly assumes that the marginal intermediaries are the same across different markets. Departures from this assumption may alter the magnitude but not the mechanism of demand propagation.

⁴³The cross-multiplier between the traded FX factors and these five non-FX asset classes are reported in Table SA4 of the Supplemental Appendix.

7 Conclusion

In conclusion, this paper studies the propagation of demand shocks through traded risk factors. If asset prices respond to risks and marginal investors can diversify risks across assets, then demand shocks propagate by affecting non-diversifiable risks, as captured by traded risk factors. We identify the most traded risk factors by extending the concept of priced non-diversifiable risks (Ross, 1976) to a representative intermediary framework (He and Krishnamurthy, 2017) and developing a method that integrates trading and returns data.

Applying the method to FX, we uncover the Dollar, the Carry, and the Euro-Yen Residual factors. These three factors explain 90% of the non-diversifiable risk intermediaries absorb in FX trading, and IV estimates show factor prices rise by 5–30 basis points per \$1 billion of factor demand. Hence, a demand shock to one currency propagates by changing the demand for these traded risk factors, affecting first the factors’ prices and then the price of other currencies with shared exposures. The same logic leads to demand propagation across non-currency assets through shared currency risk. In short, we link trading quantities and asset prices (Froot and Ramadorai, 2008; Kojien and Yogo, 2019) through risks, underscoring the role of common risk in cross-asset dynamics (Haddad and Muir, 2021; Du, Hébert, and Huber, 2023).

A distinguishing feature of our paper is the use of traded risk factors to inform demand propagation across 17 currencies and 5 major non-FX asset classes. The mechanism rests on three empirically measurable objects: how demand shocks change non-diversifiable risks (q); how prices adjust to compensate intermediaries for absorbing additional risks (λ); and how each asset is exposed to these risks (β). Integrating these elements reveals rich transmission patterns, where demand shocks in one market propagate to others with varying magnitudes and even directions. As asset markets become increasingly interconnected, understanding how demand shocks propagate through common risk exposure is crucial for predicting and managing systematic market dynamics.

A Appendix for Proofs

This appendix provides proofs omitted in the main text.

A.1 Solution for Traded Risk Factors

In this appendix, we present solutions for traded risk factors in Section 2.2.

We conduct Cholesky decomposition of $\text{var}(\mathbf{r})$ as $\mathbf{U}^\top \mathbf{U}$. Then, we define $\mathbf{g}_k = \mathbf{U}\mathbf{b}_k$ for each factor k . Equation (1) implies that the factor-level flow is

$$q_k = (\mathbf{b}_k^\top \text{var}(\mathbf{r}) \mathbf{b}_k)^{-1} \mathbf{b}_k^\top \text{var}(\mathbf{r}) \mathbf{f} = (\mathbf{g}_k^\top \mathbf{g}_k)^{-1} \mathbf{g}_k^\top \mathbf{U} \mathbf{f}. \quad (\text{A1})$$

Moreover, the sequential optimization problem (3) becomes

$$\begin{aligned} \max_{\mathbf{g}_k} & (\mathbf{g}_k^\top \mathbf{g}_k)^{-1} \text{var}(\mathbf{g}_k^\top \mathbf{U} \mathbf{f}) \\ \text{s.t.} & \mathbf{g}_k^\top \mathbf{g}_j = 0 \text{ for } k \neq j. \end{aligned} \quad (\text{A2})$$

This becomes a standard PCA problem that is solved by the eigenvalue decomposition of the matrix $\text{var}(\mathbf{U} \mathbf{f})$ (Jolliffe, 1986). The eigenvectors are $\mathbf{g}_k$ and the corresponding eigenvalues are proportional to the fraction of explained variance. Once we obtain $\mathbf{g}_k$, the portfolio weights are obtained by $\mathbf{b}_k = \mathbf{U}^{-1} \mathbf{g}_k$.

A.2 Proof of Proposition 1

Simplifying equation (7), we have

$$\begin{aligned} & \mathbb{E} \left[-\exp \left(-\sum_{k=1}^K \gamma_k y_k (\mathbf{b}_k^\top \mathbf{R} - R_F \Delta p_k) \right) \right] \\ &= -\exp \left[-\sum_{k=1}^K \left(\gamma_k y_k \mathbb{E}[\mathbf{b}_k^\top \mathbf{R}] - \gamma_k R_F y_k \Delta p_k - \gamma_k^2 y_k^2 \text{var}(\mathbf{b}_k^\top \mathbf{R})/2 \right) \right], \end{aligned} \quad (\text{A3})$$

where the last equality uses the fact that $\text{cov}(\mathbf{b}_k^\top \mathbf{R}, \mathbf{b}_j^\top \mathbf{R}) = 0$ for $k \neq j$. Taking the first-order condition with respect to y_k and evaluating it at the optimal $y_k = -\hat{q}_k/\mu$, we obtain

$$\Delta p_k = \frac{\text{var}(\mathbf{b}_k^\top \mathbf{R}) \gamma_k \hat{q}_k / \mu + \mathbb{E}[\mathbf{b}_k^\top \mathbf{R}]}{R_F}. \quad (\text{A4})$$

Using the fact that $\Delta p_k = 0$ when $\hat{q}_k = 0$, along with the assumption that $\text{var}(\mathbf{r}) = \text{var}(\mathbf{R})$, we derive equation (8).

A.3 Proof of Proposition 2

Because factors have uncorrelated returns by equation (3), we can project the return of any currency n onto the factors and obtain

$$r_n = \sum_{k=1}^K \beta_{n,k} \mathbf{b}_k^\top \mathbf{r} + e_n, \quad (\text{A5})$$

where e_n is the idiosyncratic return of currency n that is uncorrelated with any factor $\mathbf{b}_k^\top \mathbf{r}$. Hence, by the law of one price and equation (8), the price response of currency n is

$$\Delta \hat{p}_n = \sum_{k=1}^K \beta_{n,k} \Delta p_k = \sum_{k=1}^K \lambda_k \hat{q}_k \text{var}(\mathbf{b}_k^\top \mathbf{r}) \beta_{n,k}. \quad (\text{A6})$$

Therefore, we have

$$\frac{\partial \Delta \hat{p}_n}{\partial \hat{q}_k} = \frac{\partial \Delta p_k}{\partial \hat{q}_k} \times \frac{\partial \Delta \hat{p}_n}{\partial \Delta p_k} = \lambda_k \text{var}(\mathbf{b}_k^\top \mathbf{r}) \times \beta_{n,k}. \quad (\text{A7})$$

Next, equation (6) implies that $\partial \hat{q}_k / \partial \hat{f}_m = \beta_{m,k}$. Hence, we have proved

$$\frac{\partial \Delta \hat{p}_n}{\partial \hat{f}_m} = \sum_{k=1}^K \frac{\partial \hat{q}_k}{\partial \hat{f}_m} \times \frac{\partial \Delta \hat{p}_n}{\partial \hat{q}_k} = \sum_{k=1}^K \beta_{m,k} \times \lambda_k \text{var}(\mathbf{b}_k^\top \mathbf{r}) \times \beta_{n,k}. \quad (\text{A8})$$

B Fraction of Return Variance Explained by Factor Flows

This appendix measures how much of each factor's return variance comes from factor flows. Equilibrium flows may carry information, so price impacts have two parts: a permanent information component and a temporary demand component. Our estimate λ_k captures the demand component, and we have shown that its impact reverts within one month. We now compute, across different horizons, the share of return variance explained by this temporary effect. As the horizon lengthens, the temporary impact decays and accounts for a smaller fraction of total variance.

Consider stochastic trading flow over the horizon $[0, T]$. During an infinitesimal interval dt , the flow shock for factor k has standard deviation $\sigma(q_{k,t})\sqrt{dt}$, where $\sigma(q_{k,t})$ is the annualized flow volatility. Each unit of flow moves the price by $\lambda_k \sigma(r_{k,t})^2$, with $\sigma(r_{k,t})$ denoting the annualized return volatility. Hence the contemporaneous price change generated by the shock equals $\lambda_k \sigma(r_{k,t})^2 \sigma(q_{k,t})\sqrt{dt}$. Assuming this impact decays linearly to zero within one month (1/12 years), a shock arriving at time t still affects the price at the terminal date

Figure A1: **Factor flow contribution to return variance**

Notes: This figure displays the share of return variance that comes from the impact of flow, which is derived in equation (A10).

T by the factor $\max\{0, 1 - 12(T - t)\}$. Accordingly, the proportion of the terminal price variance attributable to order flow is

$$\frac{\int_0^T (\max\{0, 1 - 12(T - t)\} \lambda_k \sigma(r_{k,t})^2 \sigma(q_{k,t}))^2 dt}{\int_0^T \sigma(r_{k,t})^2 dt}, \quad (\text{A9})$$

which measures the share of total variance over $[0, T]$ that arises from temporary price impacts of order-flow shocks. This fraction simplifies to

$$\begin{cases} \lambda_k^2 \sigma(r_{k,t})^2 \sigma(q_{k,t})^2 (1 - 12T + 48T^2) & 0 < T \leq \frac{1}{12}, \\ \frac{\lambda_k^2 \sigma(r_{k,t})^2 \sigma(q_{k,t})^2}{36T} & T > \frac{1}{12}. \end{cases} \quad (\text{A10})$$

Figure A1 shows that for the three factors, flows explain roughly 10–35% of return variance at the 1-week horizon, 5–15% at one month, and rapidly less at longer horizons.

Supplemental Appendix of “Demand Propagation Through Traded Risk Factors”

A Invariance of Factors under Alternative Numeraire Currency

In this appendix, we prove that the factors constructed in Appendix A.1 remain unchanged when we alter the numeraire currency used to measure demand shocks and returns.

Suppose we switch from using USD to the N -th currency as the numeraire. We denote the demand shock from the N -th currency to the n -th currency as $\tilde{f}_n$ for $n = 1, 2, \dots, N-1$, and the demand shock from the N -th currency to USD as $\tilde{f}_N$. Recall that f_n represents the demand shock from USD to the n -th currency. Because each demand shock f_n (for $n = 1, 2, \dots, N-1$) can be broken down into a component from USD to the N -th currency and another from the N -th currency to the n -th currency, we can express this transformation as follows:

$$\tilde{\mathbf{f}} = (\tilde{f}_1, \tilde{f}_2, \dots, \tilde{f}_{N-1}, \tilde{f}_N)^\top = \left(f_1, f_2, \dots, f_{N-1}, -\sum_{n=1}^N f_n \right)^\top = \mathbf{C}\mathbf{f}, \quad (\text{SA1})$$

where we define the matrix

$$\mathbf{C} := \begin{pmatrix} 1 & 0 & \dots & 0 & 0 \\ 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & 1 & 0 \\ -1 & -1 & \dots & -1 & -1 \end{pmatrix}. \quad (\text{SA2})$$

Similarly, returns are now measured relative to the N -th currency. Specifically, $\tilde{r}_n$ for $n = 1, 2, \dots, N-1$ represents the return from borrowing at the N -th currency's riskfree rate to invest in the n -th currency's riskfree rate. Similarly, $\tilde{r}_N$ denotes the return from borrowing at the N -th currency's riskfree rate to invest in the USD riskfree rate. The transformation of returns can thus be described as follows:

$$\tilde{\mathbf{r}} = (\tilde{r}_1, \tilde{r}_2, \dots, \tilde{r}_{N-1}, \tilde{r}_N)^\top = (r_1 - r_N, r_2 - r_N, \dots, r_{N-1} - r_N, -r_N)^\top = \mathbf{C}^\top \mathbf{r}. \quad (\text{SA3})$$

Now, we apply Appendix A.1 to analyze the factors using $\tilde{\mathbf{r}}$ and $\tilde{\mathbf{f}}$. Specifically, the variance of $\tilde{\mathbf{r}}$, given by $\text{var}(\tilde{\mathbf{r}}) = \mathbf{C}^\top \text{var}(\mathbf{r})\mathbf{C}$, can be decomposed as $\mathbf{C}^\top \mathbf{U}^\top \mathbf{U} \mathbf{C} = \tilde{\mathbf{U}}^\top \tilde{\mathbf{U}}$,

where $\tilde{\mathbf{U}} := \mathbf{U}\mathbf{C}$. Subsequently, the eigenvalue decomposition is transformed to

$$\tilde{\mathbf{U}}\text{var}(\tilde{\mathbf{f}})\tilde{\mathbf{U}}^\top = \mathbf{U}\mathbf{C}\mathbf{C}\text{var}(\mathbf{f})\mathbf{C}^\top\mathbf{C}^\top\mathbf{U}^\top = \mathbf{U}\text{var}(\mathbf{f})\mathbf{U}^\top, \quad (\text{SA4})$$

where we use the fact that $\mathbf{C}\mathbf{C} = \mathbf{I}_N$. This derivation reveals that the eigenvectors $\mathbf{g}_k$ and eigenvalues are invariant. The resulting portfolio weights under the new numeraire currency are given by $\tilde{\mathbf{b}}_k = \tilde{\mathbf{U}}^{-1}\mathbf{g}_k = \mathbf{C}^{-1}\mathbf{U}^{-1}\mathbf{g}_k = \mathbf{C}^{-1}\mathbf{b}_k$. Hence, the factor returns also remain invariant, because $\tilde{\mathbf{b}}_k^\top \tilde{\mathbf{r}} = \mathbf{b}_k^\top (\mathbf{C}^{-1})^\top \mathbf{C}^\top \mathbf{r} = \mathbf{b}_k^\top \mathbf{r}$.

B Inclusion of Non-spot FX Derivatives Trading Flows

Foreign exchange trades can be executed in the spot market and in the derivatives market of forwards and swaps. Trading in the derivatives market can expose the intermediary to foreign exchange risk. Consider a customer-initiated trade of selling \$100-worth of JPY 1-month forward against USD. In the absence of other trades, an intermediary who has no capital, maintains a net neutral FX exposure, and serves as the counterparty in this trade, must satisfy the obligation to deliver \$100 in a month by setting aside $\$100/(1 + r_{1M}^\$)$ today, where $r_{1M}^\$$ is the 1-month USD risk-free rate. Similarly, the intermediary will sell $100/(1 + r_{1M}^{\text{JPY}})$ of JPY today to both fund his USD purchase and to ensure FX neutrality when he receives the promised delivery from the customer. To the intermediary, therefore, a forward contract is no different from a spot transaction but for the fact that the amount of implied FX exposure in a forward is less than its notional.

Because we are interested in measuring all the FX risks that intermediaries have to bear by accommodating customer trading flows, we need to consider trading flows in both the spot and the derivatives market.⁴⁴ In this appendix, we explore the difference between trading flows into the spot versus the derivatives market and the implications of using trading data in only one of the two markets in our analysis.

We start by examining the observed trading flows into individual currencies. The triennial survey conducted by the Bank of International Settlement (BIS) indicates that there is twice as much trading flow in the FX derivatives market as in the spot market (Appendix Figure SA1). Appendix Table SA1 reports the correlation between the net flow into the spot versus the derivatives market for each of the six major currencies in our sample. The absolute strength of the correlation ranges between 0.17 and 0.62, suggesting sizeable comovements in trading flows between the spot and the derivatives FX market.

Comovements in observed trading flows could be induced by common risk factors that

⁴⁴We treat swaps as a spot transaction plus a forward contract.

Figure SA1: **FX Daily Turnover Against USD**

Notes: This figure plots the global daily volume of foreign exchange spot versus forward and FX swaps transactions involving USD. Daily volume is calculated as the average of all trading days in April of the survey year. The survey is conducted triennially from 2001 to 2022 by BIS.

Table SA1: **Currency-Specific Correlation between Net Trading Flow in Spot vs. Non-Spot Derivatives**

AUD	CAD	CHF	EUR	GBP	JPY
-0.48	0.17	-0.54	-0.39	-0.62	-0.35

Notes: This table reports the correlation between net flows into individual currencies in the spot market and in the non-spot derivatives market.

are present in both the spot and the derivatives market. If so, trading data from either market alone should be sufficient to recover the traded FX risk factors. At the same time, if there are strong comovements in trading flows to the traded FX factors, then relying on data from only one market risks introducing measurement error in the estimation of price sensitivity to risks.

In Appendix Table SA2, we compare the traded FX factors recovered separately from the spot market and the non-spot derivatives market. The top row shows the correlation between *returns* of factors estimated using only one of the individual markets. For the first factor, the return correlation is close to 1, and this correlation is 77% for the second factor and 73% for the third factor. Such pronounced relationships underscore the robustness of the underlying factors and suggest that the same risk factors drive trading across the spot

Table SA2: **Correlation between Returns and Flows to Factors Estimated in Different Samples**

	Factor 1	Factor 2	Factor 3
Return	0.99	0.77	0.73
Flow	-0.51	-0.13	-0.35

Notes: This table reports the correlation between the returns and flows to each of the top three traded risk factors as estimated in the spot market versus in the non-spot derivatives market.

and the derivatives market. The bottom row shows the correlation between *flows* to factors estimated using only one of the individual markets. The correlations are -0.51, -0.13, and -0.35 for the three factors, respectively.

The marked association between factor returns and factor flows points to the strength and limitation of using only data in the spot market. On the one hand, the tight correlation between factor returns constructed using data from individual markets shows that the spot market alone is sufficient to recover the underlying risk factors because these factors drive trading in both the spot and derivatives markets. On the other hand, using only data from the spot market is likely insufficient for estimating these factors' price sensitivity to risks because the spot market data alone may not provide an appropriate measure of the flow changes. Estimating price sensitivity to risks requires instrumenting for the flow that induces the observed price change. As spot flows and derivatives flows are highly correlated, it is empirically difficult to isolate variations in just the spot flow. Specifically, because factor flows in the spot market are negatively correlated with factor flows in the derivatives market, instrumenting for just the spot market will overestimate factor flows, biasing the estimate to imply smaller price sensitivity to risks.

C Additional Figures and Tables

Table SA3: **Correlation Between Traded FX Factors in Full Sample vs. Subsamples**

		Factor 1	Factor 2	Factor 3
Return	Pre 2020	0.97	0.83	0.83
	Post 2020	1.00	0.97	0.89
Flow	Pre 2020	0.98	0.82	0.81
	Post 2020	0.99	0.96	0.81

Notes: In this table, we report the correlation between returns and flows of the traded FX factors constructed based on the full sample versus returns and flows of the traded FX factors constructed based on different subsamples. Pre-2020 refers to the sample period from September 2012 to December 2019, while post-2020 refers to the sample period from January 2020 to December 2023.

Table SA4: **Demand Propagation Between Traded FX Factors and Non-FX Asset Classes**

	CDS	Comm	CorpBond	Opt	UST
Dollar	-2.0	-5.0	-2.8	-4.4	-0.5
Carry	3.7	1.6	3.7	6.1	-2.3
Euro-Yen	-2.5	-10.3	-7.3	-6.6	-1.6

Notes: This table uses Proposition 2, the estimated factor-level price sensitivity to risks λ_k from Table 5, and the beta loadings of assets to factors (signs illustrated in Figure 3) to compute cross-multiplier between traded FX factors and six non-FX asset classes. Each entry represents the price movement in bps of a column asset, as induced by a \$1 billion demand shock into a traded FX factor.

Figure SA2: **Cumulative Flow by Investor Type to Traded FX Factors**

(a) **Dollar Factor**

(b) **Carry Factor**

(c) **Euro-Yen Factor**

Notes: This figure displays the cumulative flows by customer type into the top three traded FX factors between September 2012 and December 2023. The Net Total represents the net customer flows that Banks (intermediaries) need to absorb.

Figure SA3: **Reversion of Contemporaneous Price Response**

Notes: This figure shows the cumulative price responses for the traded FX factors. These responses, measured per billion of demand shocks, are estimated by regressing the return from week $t-1$ to $t+h$ (for $h = 0, 1, 2, 3, 4$) on the instrumented flow from week $t-1$ to t . The shaded area represents the 95% confidence interval based on Newey-West standard errors with the bandwidth selected according to the [Newey and West \(1994\)](#) procedure.

Figure SA4: **Decomposition of Asset-Class Returns Explained by Traded FX Factors Outside of Crises**

Notes: This figure decomposes the returns of individual assets into the Dollar, the Carry, and the Euro-Yen factors. The decomposition is achieved by regressing asset class monthly average excess return between 2000-02 and 2023-12 on returns from the three traded FX factors. We exclude the GFC (2007-07 through 2010-07) and COVID (2020-01 through 2020-06) period. The returns from CDS are available starting 2007-04. The returns from Opt end in 2022-12. It reports both the marginal R^2 values attributed to each factor and the total R^2 . The positive and negative signs illustrate the direction of the beta loadings.
